

## About complexity

We define the class informally  $P$  in the following way:

$P =$  The set of all problems that can be solved by a polynomial time algorithm, i.e., an algorithm that runs in time  $O(n^k)$  in the worst case, where  $k$  is some integer and  $n$  is the size of the input.

We can contrast this class with

$EXP =$  The set of all problems that can be solved by an exponential time algorithm, i.e., an algorithm that runs in time  $O(c^{n^k})$  in the worst case, where  $k$  is some integer,  $c > 1$  some real number and  $n$  is the size of the input.

It is universally agreed that an algorithm is efficient if and only if it is polynomial. This makes it critical to define the size of the input in a "correct way". For instance, we must be careful if we have numbers as input.

## Using randomness in algorithms

The algorithms we have studied are deterministic. We will now discuss algorithms that use randomness. The randomness in computation can be observed as

- a. Randomness in the output. These algorithms are often called *probabilistic* algorithms.
- b. Randomness in running time. These algorithms are often called *randomized* algorithms.

## **Probabilistic algorithms**

We will start with a study of a special probabilistic algorithm: The Miller-Rabin algorithm.

We will define a class of problems belonging to a class called RP (Randomized Polynomial). We will see that the problem of deciding if a number is composed belongs to RP.

In order to set the scene for the Miller-Rabin algorithm, we will start with a description of some number theoretical algorithms.

## Number theoretical algorithms

Number theoretical algorithms are algorithms handling problems such as deciding if a number is a prime, finding greatest common divisor and so on. Input to the algorithms are integers. The natural measure of the size of the input is the logarithm of the numbers.

**Ex:** Test if a number is a prime.

PRIME( $n$ )

- (1) **for**  $i \leftarrow 2$  **to**  $\sqrt{n}$
- (2)     **if**  $i|n$
- (3)         **return** Not prime
- (4) **return** Prime

This algorithm has complexity  $O(\sqrt{n})$ . It is too slow for large numbers. We would like to have an algorithm that runs in time  $O((\log n)^k)$  for some  $k$ .

## Greatest Common Divisor

**Greatest common divisor:**  $\gcd(a, b)$  = is the largest integer that divides both  $a$  and  $b$ .

### Euclides' algorithm:

The  $\gcd(a, b)$  can be computed by the following method:

$$r_1 = a \bmod b$$

$$r_2 = b \bmod r_1$$

$$r_3 = r_1 \bmod r_2$$

...

$$r_{n+1} = r_{n-1} \bmod r_n = 0$$

Then  $\gcd(a, b) = r_n$ .

It is easy to verify that  $r_{i+2} < \frac{r_i}{2}$  for all  $i$ . This means that the algorithm stops after  $O(\log n)$  step. So the algorithm is efficient.

The algorithm can be implemented recursively.

**EUKLIDES**( $a, b$ )

(1) **if**  $b = 0$

(2)     **return**  $a$

(3) **return** **EUKLIDES**(  $b, a \bmod b$  )

If  $\gcd(a, b) = d$  there are integers  $x, y$  such that  $ax + by = d$ . ( $x, y$  can be negative). In fact,  $d$  is the smallest integer  $> 0$  on that form. The integers  $x, y$  can be found by a modified version of Euclides' algorithm:

MOD-EUKLIDES( $a, b$ )

(1) **if**  $b = 0$

(2)     **return** ( $a, 1, 0$ )

(3)      $(d', x', y') \leftarrow$  MOD-EUKLIDES( $b, a$   
          mod  $b$ )

(4)      $(d, x, y) \leftarrow (d', y'x' - [\frac{a}{b}]y')$

(5)     **return** ( $d, x, y$ )

**Finding the inverse:** If  $\gcd(a, n) = 1$  there are integers  $x, y$  such that  $ax + ny = 1$ . Then  $x = a^{-1} \pmod{n}$ . So we can find  $a^{-1}$  by using MOD-EUKLIDES( $a, n$ ).

## Modular exponentiation

In cryptography it is important to be able to compute  $a^b \bmod n$  for very large numbers in an efficient way. The following simple algorithm is not efficient:

POT( $a, b, n$ )

- (1)  $d \leftarrow 1$
- (2) **for**  $i \leftarrow 2$  **to**  $b$
- (3)      $d \leftarrow d \cdot a \bmod n$
- (4) **return**  $d$

The following modified algorithm, though, is efficient:

MOD-EXP( $a, b, n$ )

- (1)  $d \leftarrow 1$
- (2) Let  $(b_k, b_{k-1}, \dots, b_0)$  be the binary representation of  $b$
- (3) **for**  $i \leftarrow k$  **to**  $0$
- (4)      $d \leftarrow d \cdot d \bmod n$
- (5)     **if**  $b_i = 1$
- (6)          $d \leftarrow d \cdot a \bmod n$
- (7) **return**  $d$

## To decide if a number is a prime

**Fermat's Theorem:** If  $p$  is a prime and  $a$  is an integer such that  $a \nmid p$  then  $a^{p-1} \equiv 1 \pmod{p}$ .

We can set  $a = 2$ . If  $n$  is such that  $2^{n-1} \not\equiv 1 \pmod{n}$  then  $n$  cannot be a prime. Therefore, we can use the following algorithm to test if  $n$  is a prime:

FERMAT( $n$ )

- (1)  $k \leftarrow \text{MOD-EXP}(2, n - 1, n)$
- (2) **if**  $k \not\equiv 1 \pmod{n}$
- (3)     **return** FALSE
- (4) **return** TRUE

If FERMAT returns FALSE we know for sure that  $n$  is not a prime. But unfortunately, FERMAT might return TRUE even if  $n$  is not a prime. For instance,  $2^{340} \equiv 1 \pmod{341}$  but 341 is not a prime.

We can use a so *probabilistic* algorithm which randomly chooses a number  $a$  in  $[2, n - 1]$  and does a Fermat test with  $a$ .

PROB-FERMAT( $n, s$ )

- (1) **for**  $j \leftarrow 1$  **to**  $s$
- (2)      $a \leftarrow \text{RANDOM}(2, n - 1)$
- (3)      $k \leftarrow \text{MOD-EXP}(a, n - 1, n)$
- (4)     **if**  $k \not\equiv 1 \pmod{n}$
- (5)         **return** FALSE
- (6) **return** TRUE

The algorithm is probabilistic in the sense that it can give different answers at different times even if it starts with the same input. The following must, however, be true:

if  $n$  is a prime then the algorithm must return TRUE. This means that the algorithm returns FALSE then we know that  $n$  is not a prime. So FALSE is the only definite answer we can get.

$$P(n \text{ is not prime} \mid \text{The algorithm returns FALSE}) = 1$$

What about the probability

$$P(n \text{ is prime} \mid \text{The algorithm returns TRUE})?$$

It can be shown that for almost all non-prime  $n$  we get:

$$P(\text{The algorithm returns FALSE}) > \frac{1}{2}.$$

(For primes  $n$  we have

$$P(\text{The algorithm returns TRUE}) = 1.)$$

Problems are caused by so called **Carmichael numbers**.

## Carmichael numbers

A Carmichael number is a non-prime integer  $n$  such that  $a^{n-1} \equiv 1 \pmod{n}$  for all  $a \in [2, n-1]$ . The smallest Carmichael number is 341.

$P(\text{The algorithm returns TRUE} \mid n \text{ is a Carmichael number}) = 1.$

In order to handle Carmichael numbers we can use the following algorithm:

WITNESS( $a, n$ )

- (1) Let  $n - 1 = 2^t u$ ,  $t \geq 1$ , where  $u$  is odd
- (2)  $x_0 \leftarrow \text{MOD-EXP}(a, u, n)$
- (3) **for**  $i \leftarrow 1$  **to**  $t$
- (4)      $x_i \leftarrow x_{i-1}^2 \pmod{n}$
- (5)     **if**  $x_i = 1$  och  $x_{i-1} \neq 1$  och  $x_{i-1} \neq n - 1$
- (6)         **return** TRUE
- (7)     **if**  $x_t \neq 1$
- (8)         **return** TRUE
- (9)     **return** FALSE

Observe that WITNESS returns true if  $n$  is composite and not a prime. The test is traditionally described like this.

The following can be shown for WITNESS:

$P(\text{ WITNESS returns TRUE } | n \text{ is not prime } ) > \frac{1}{2}$   
for all  $n$ . If you make repeated calls to WITNESS can get arbitrarily high probability for a correct answer. This version of the algorithm is called Miller - Rabin's Test.

MILLER-RABIN( $n, s$ )

- (1) **for**  $j \leftarrow 1$  **to**  $s$
- (2)      $a \leftarrow \text{RANDOM}(1, n - 1)$
- (3)     **if** WITNESS( $a, n$ )
- (4)         **return** Not prime
- (5) **return** Prime

Here

$P(\text{ The algorithm returns Prime } | n \text{ is prime}) = 1.$

$P(\text{ The algorithm returns Not prime } | n \text{ is not prime } ) > 1 - \frac{1}{2^s}.$

It is, of course, also interesting to study the "reversed" conditional probabilities:

$$P(n \text{ is not prime} \mid \text{The algorithm returns Not prime}) = 1.$$

The probability

$P(n \text{ is prime} \mid \text{The algorithm returns Prime})$  is trickier. It can be computed as

$$\frac{P(n \text{ is prime and the algorithm returns Prime})}{P(\text{The algorithm returns Prime})} = \frac{P(n \text{ is prime})}{P(\text{The algorithm returns Prime})}$$

But then we need to know  $P(n \text{ is prime})$ . If we know that the probability is  $\alpha$  we can use Bayes' law to show that

$$P(n \text{ is prime} \mid \text{The algorithm returns Prime}) > \frac{2^s}{2^s + (\frac{1}{\alpha} - 1)}.$$

Since August 2002 it is known that there is an algorithm that decides primality (in the usual non-probabilistic sense) in polynomial time. This algorithm is much more complicated and slower than Miller-Rabin's algorithm.

## Monte Carlo algorithms

Suppose that we have a decision problem, i.e. a problem with yes/no as answer. We say that  $F$  is a **Yes-based Monte Carlo algorithm** for solving the problem if  $F$  is polynomial and:

1. If the answer to the problem is yes, then  $F(x) = Yes$  with probability  $> \frac{1}{2}$ .
2. If the answer to the problem is no, then  $F(x) = No$  with probability 1.

No-based Monte Carlo algorithms are defined in the obvious, symmetrical way.

**Definition:** The class RP is the set of all problems that can be solved by a Yes-based Monte Carlo algorithm.

It is easily seen that  $P \subseteq RP$ .

We have seen that the problem to tell if a number is composite is in RP.

## Another algorithm

Is the polynomial

$$f(x, y) = (x - 3y)(xy - 5x)^2 - 10x^3y + 25x^3 + 3x^2y^3 + 30x^2y^2 - 75x^2y$$

identically equal to 0?

**Test:** Choose some values  $x_i, y_i$  randomly and test if  $f(x_i, y_i) = 0$ .

Two possibilities:

1.  $f(x_i, y_i) \neq 0$ . Then  $f \neq 0$ .
2.  $f(x_i, y_i) = 0$  for all chosen values  $x_i, y_i$ .  
What is then the probability for  $f = 0$ ?

**Theorem:** If  $f(x_1, \dots, x_m)$  is not identically equal to 0 and each variable occurs with degree at most  $d$  and  $M$  is an integer, then the number of zeros in the set  $\{0, 1, \dots, M - 1\}^m$  is at most  $mdM^{m-1}$ . This gives us:

$$P[\text{A random integer in } \{0, 1, \dots, M-1\}^m \text{ is a zero}] = \frac{1}{mdM^{m-1}} = \delta.$$

This means that if we have done  $k$  tests indicating  $f = 0$ , then  $P[f = 0] \geq (1 - \delta)^k$ .

This means that to tell if a polynomial is not zero is a problem in RP.

## **RP and similar classes**

So if we let PRIME be the problem to tell if a number is a prime or not we have  $\text{PRIME} \notin \text{RP}$ . Instead of using a Yes-based MC algorithm we can use a No-based one. Then we get a class  $\text{coRP}$ , i.e. the class of problems that can be solved by No-based MC algorithms.

We have  $\text{PRIME} \in \text{coRP}$ .

## ZPP

And now we define  $ZPP = RP \cap \text{coRP}$

Problems in the class ZPP can be solved by machines  $M$  with the following properties:

- a.  $M$  returns one of Yes, No, Undecided.
- b. If  $M$  returns Yes then the true answer is Yes and if  $M$  returns No then the true answer is no.
- c. The probability that  $M$  returns undecided is  $< \frac{1}{2}$ .

In fact, it can be shown that  $\text{PRIME} \in ZPP$ .

## Randomized algorithms

Randomized algorithms are deterministic in the sense that the output is unique. But the running time can be different in different starts with the same input. The most famous example is the randomized version of QuickSort. The randomization is that we choose the pivot element in the partition randomly.

QuickSort( $v[i..j]$ )

- (1) **if**  $i < j$
- (2)      $m \leftarrow \text{Random\_Partition}(v[i..j], i, j)$
- (3)     QuickSort( $v[i..m]$ )
- (4)     QuickSort( $v[m + 1..j]$ )

The complexity analysis is more complicated than it is for Merge sort. It can nevertheless be shown that the complexity is  $O(n \log n)$  *in the mean*.

## A similar problem: Finding the median

If we have an array  $v[1\dots n]$  the problem of finding the median is the problem of finding an element  $v[i]$  such that exactly  $\lfloor \frac{n}{2} \rfloor$  elements are smaller than  $v[i]$ . We can obviously find the median in time  $O(n \log n)$ . But if we use a probabilistic algorithm we can find the median in time  $(On)$  *in the mean*. We define a function  $Select(v[i\dots j], k)$  which finds the  $k$ th element (in sorted order) in the subarray  $v[i\dots j]$ . (We assume that  $k \leq j - i + 1$ .) Then  $Select(v[1\dots n], \lfloor \frac{n}{2} \rfloor)$  will give us the median.

$Select(v[i\dots j], k)$

- (1) **if**  $i = j$
- (2)     Return  $v[i]$
- (3)  $p \leftarrow Partition(v[i..j])$
- (4)  $q \leftarrow p - i + 1$
- (5) **if**  $q = k$
- (6)     Return  $v[p]$
- (7) **if**  $k < q$
- (8)     Return  $Select(v[i\dots p - 1], k)$
- (9)     Return  $Select(v[p + 1\dots j], k - q)$

It can be shown that if  $E(T(n))$  is the mean value of the time complexity, we have  $E(T(n)) \leq \frac{2}{n} \sum_{k=\lfloor \frac{n}{2} \rfloor}^{n-1} E(T(k)) + O(n)$ . From this, we can prove that  $T(n) \in O(n)$ .

## **Extra: Sorting in linear time**

Sorting algorithms that only use comparisons between elements can never be faster than  $\Theta(n \log n)$ . But there are algorithms which use extra information about the elements. For instance, if we want to sort integers we might know upper and lower bounds for the integers. Then it is possible to sort in linear time.

## Counting sort

Assume that we have  $n$  objects  $A[1..n]$  with keys which are integers in  $[1, k]$ . The following algorithm sorts in time  $O(n + k)$ :

CountingSort( $A, B, k$ )

- (1) **for**  $i = 1$  **to**  $k$
- (2)      $C[i] \leftarrow 0$
- (3) **for**  $i = 1$  **to**  $n$
- (4)      $C[A[i]] \leftarrow C[A[i]] + 1$
- (5) **for**  $i = 2$  **to**  $k$
- (6)      $C[i] \leftarrow C[i - 1] + C[i]$
- (7) **for**  $j = 1$  **to**  $n$
- (8)      $B[C[A[j]]] \leftarrow A[j]$
- (9)      $C[A[j]] \leftarrow C[A[j]] - 1$

When the algorithm ends, the array  $B$  is  $A$  in sorted order.
